MoPR Geospatial Hackathon

Advanced Inference Strategies & Innovation Report

Problem Statement 1 — AI-Based Feature Extraction from SVAMITVA Drone Orthophotos

Geo-Intel Lab / IITTNiF — March 2026

Document structure

- Section 1 — Strategy overview: detailed discussion of all four inference strategies plus the edge-adjacent tracking strategy and the moss-lake edge case
- Section 2 — Cowork implementation prompt: production-ready prompt for the coding agent
- Section 3 — Literature review: academic grounding for each strategy with key papers, findings, and direct relevance to this project

Section 1 — Strategy Overview

This section provides a detailed discussion of five inference-time strategies proposed for the SVAMITVA drone orthophoto segmentation pipeline, followed by a note on a specific field observation (moss-covered lake) and how to handle it in outputs without DSM.

1.1 Confidence Maps & Surveyor Feedback Tool

This is the strongest of the five strategies both technically and from a governance standpoint. It transforms the model from a one-shot black box into a **human-in-the-loop system** that improves over time.

Technical mechanism

Standard segmentation models output a single argmax class prediction per pixel. The innovation here is to output the softmax probability of the predicted class alongside the argmax — producing a per-pixel confidence score between 0 and 1. This is available from any trained segmentation model at zero additional training cost; it requires only a small change to the inference script.

Two approaches exist for richer uncertainty: **softmax confidence** (simple, already available), and **Monte Carlo Dropout** (MC Dropout), where dropout layers are kept active at inference time, the model is run N times with different dropout masks, and the variance across runs is used as an uncertainty estimate. MC Dropout adds roughly 10–20% inference overhead for N=5 passes but provides a principled Bayesian uncertainty measure.

Governance application — the surveyor tool

The confidence map feeds a structured field verification workflow. Low-confidence polygons (confidence below a tunable threshold, e.g. 0.65) are exported to a separate GPKG layer and provided to a field survey team. Each record contains the polygon geometry, predicted class, confidence score, and a village/tile ID. A field agent opens this layer on a phone via QGIS Mobile or a printed A4 sheet, physically verifies the classification, corrects it if needed, and returns the result. Those verified labels are then incorporated into the training set for the next fine-tuning round.

This creates a **living feedback loop**: the more villages are processed, the more verified corrections accumulate, and the model is periodically fine-tuned on this growing corpus of high-quality ground truth. The operational cost is low — a team only needs to visit the 5–15% of structures flagged as uncertain per village, not the full village.

> **Key governance insight**
>
> Confidence maps reframe the model's output from 'the AI decided X' to 'the AI is 91% confident on RCC rooftops and flags 8% of structures for field verification.' This is a product a district collector can trust and act on.

Output format

- Extra band in COG raster: float32 confidence score per pixel (0.0–1.0)
- GPKG attribute: confidence (float) on each building/road/water polygon
- Separate GPKG layer: low_confidence_flags with tile_id, row, col, mean_confidence, geom_wkt for surveyor routing

1.2 Tile Context Inference (3×3 Neighbourhood Re-inference)

This strategy addresses a fundamental limitation of all tile-based segmentation systems: **edge pixels lack spatial context**. A model operating on an isolated 512×512 tile cannot see what lies beyond its boundary, so a road that exits the right edge or a waterbody that spans multiple tiles may be classified inconsistently between tiles.

Mechanism

After the initial inference pass over all tiles, low-confidence tiles (mean confidence < 0.65) are re-processed using a 3×3 superpatch approach. The flagged tile is stitched together with its 8 spatial neighbours into a 1536×1536 context image. The model runs inference on this larger patch and the central 512×512 crop is extracted and used to replace the original low-confidence prediction. This gives the model the surrounding context it lacked in the original pass.

Edge tiles without 8 full neighbours are handled by reflection padding. The approach costs approximately 9× more compute per flagged tile, but since low-confidence tiles should represent a small fraction of the total, the overall inference time increase is modest.

Why it works

The core insight is that **spatial context disambiguates spectrally similar classes**. A narrow strip that looks like bare soil at the edge of a tile may be correctly identified as a kaccha road when the full context reveals it connects two road segments. A fragment that looks like shadow may be correctly identified as water when the surrounding tiles show a pond. This is precisely the class disambiguation problem that existing tile-context literature addresses.

> **Implementation note**
> USE_CONTEXT_INFERENCE = True/False toggle in inference script. Recommended to always enable for final submission inference. Adds ~15–20% to total inference time on a typical village.

1.3 Edge-Adjacent Tile Class Tracking (Boundary Conditioning)

This is a newer and more architecturally ambitious strategy that goes beyond post-processing. The idea is to make the model aware of what classes are present at the edges of adjacent tiles, and condition its predictions on that information — particularly for tiles with ambiguous content.

Concept

At inference time, after the initial pass, the **dominant class at each edge of each tile** is extracted from its neighbour's prediction (or from the initial low-resolution pass). This edge context vector — for example, [road_kaccha, water, building, vegetation] for the four tile edges — is passed as a conditioning signal to a lightweight post-processing head or CRF step that encourages spatial consistency across tile boundaries.

This is a form of test-time conditioning that is architecturally lightweight: the base SegFormer-B2 model does not need to be retrained. The conditioning happens at the output logit level — adjacent tile class distributions can be used to bias the softmax probabilities of edge pixels toward the neighbouring class, weighted by the neighbour's confidence.

Feasibility for this project

Full architectural integration (conditioning the model's encoder with edge class tokens) requires retraining and is out of scope for the hackathon. However, a **post-processing approximation** is feasible: after the initial inference pass, edge pixels where confidence is below 0.70 and the adjacent tile's corresponding edge has a high-confidence different class are re-assigned by biasing toward spatial consistency. This is implemented as a graph-based boundary correction step in the output script, not a change to the model.

> **Research novelty**
> While CRF-based spatial consistency is well-established, applying edge-class conditioning as an explicit inference-time signal fed from neighbouring tile predictions is a relatively novel approach for tiled aerial segmentation. It is worth describing in the methodology section as a proposed enhancement.

1.4 State/Region-Wise Research-Based Parameter Adjustment

This is the most intellectually rich strategy. India's **agro-climatic diversity** means a single set of model parameters, class weights, and confidence thresholds is suboptimal across the country. RCC rooftops in

Bihar look spectrally different from RCC in coastal Andhra Pradesh. Kaccha roads in Rajasthan (pale sand, low contrast) confuse differently than kaccha roads in Kerala (red laterite, high contrast).

What gets parameterised

The regional configuration file defines overrides for:

- **Loss function class weights** — minority class weights adjusted based on regional prevalence (thatched roofs are common in Bihar, rare in Gujarat)
- **Confidence thresholds per class** — the threshold for flagging a kaccha road prediction as uncertain may be higher in semi-arid zones where the class is poorly defined
- **Post-processing parameters** — minimum polygon area, simplification tolerance, road gap-closing distance
- **Spectral normalisation priors** — background soil colour priors differ significantly between red-soil Deccan and pale alluvial Gangetic plains

Proposed zones for this dataset

Based on the SVAMITVA programme's coverage and the agro-climatic zone classification from ICAR, a practical first taxonomy would be:

- Semi-arid north (Rajasthan, parts of MP/UP) — pale sandy surfaces, sparse vegetation, high RCC prevalence in newer construction
- Humid east (Bihar, Jharkhand, Odisha) — red laterite, dense vegetation canopy, higher prevalence of thatched and kuccha structures
- Peninsular south (AP, Telangana, Karnataka, Tamil Nadu) — Mangalore tile roofs common, high spectral contrast, well-defined roads
- Coastal/deltaic (coastal Andhra, Kerala, Maharashtra coast) — dense tree canopy, frequent water body presence, tin roofs common on newer structures

Implementation approach

A *region_params.yaml* config file is loaded at the start of both training and inference. A *REGION = 'semi_arid_north'* variable at the top of the script selects the active parameter set. Each region's parameters are documented with rationale in inline comments. This is proposed as a framework even if only one region is validated during the hackathon — the architecture demonstrates scalability awareness that judges will recognise.

1.5 Road Connector Post-Processing

Segmentation models predict roads as disconnected pixel blobs, particularly where the road is occluded by tree canopy, a parked vehicle, or a structure crossing the road. The predicted GPKG ends up with fragmented road LineStrings that cannot form a routable network.

Gap-closing algorithm

After polygonizing road predictions and converting them to LineString geometries:

- Find road segment endpoints within a configurable distance (default: 15m) of another segment endpoint
- Check that the gap region does not contain high-confidence building or water predictions (verified against the confidence mask)
- If clear, insert a connecting LineString segment to close the gap
- Tag inserted segments with *road_connector: True* to distinguish model-predicted segments from algorithm-inserted connectors

The implementation uses shapely geometry operations and geopandas for the gap detection and NetworkX for optional network topology validation. This is approximately 50–80 lines of code as a **post-processing-only addition** — no model changes required.

Governance value

Connected road networks are what makes the GPKG output useful for infrastructure planning — fragmented LineStrings are useless for distance calculations or accessibility analysis. This is a direct quality-of-output improvement.

1.6 Edge Case Note — Moss-Covered Lake (No DSM Available)

A specific field observation during data review: a lake that was mostly covered in algae/moss with only a small visible open-water area. Without DSM, the primary discriminator between dense aquatic vegetation and terrestrial vegetation is lost.

How to handle without DSM

Several proxy indicators remain available from RGB alone:

- Spectral saturation: aquatic moss/algae tends to have a more uniform, muted green compared to the textured variation of terrestrial vegetation
- **Shape and planarity**: waterbodies, even moss-covered ones, tend to have smooth, convex boundaries and no internal texture variation — unlike agricultural plots or tree canopies
- **Contextual adjacency**: if the polygon is surrounded by or adjacent to confirmed water predictions or lies in a topographically low area (inferrable from surrounding road/building elevation gradients without a DSM), that is a strong prior for water
- **Size and compactness**: large flat compact polygons classified as vegetation in low-lying areas are statistically more likely to be obscured water bodies than terrestrial vegetation

Recommended submission note

In the final report's known limitations section, include a note along these lines:

Suggested report language

Spectrally ambiguous water bodies (e.g. moss/algae-covered ponds, duckweed-covered tanks, and water hyacinth-infested channels) present a classification challenge when DSM data is unavailable. In such cases, shape regularity, boundary smoothness, and contextual adjacency to confirmed water pixels are used as proxy indicators. We recommend that production deployment integrate DSM data to resolve this ambiguity, as height-flatness is the most reliable discriminator for this class of objects.

Section 2 — Cowork Implementation Prompt

The following prompt is designed to be pasted directly into Cowork (or any AI coding agent) to generate working, modular Python code implementing all five strategies. It is self-contained and includes full context so no prior conversation history is required.

```
Project context: We are building a semantic segmentation pipeline for SVAMITVA
scheme drone orthophotos of Indian villages (Ministry of Panchayati Raj hackathon).
Architecture: SegFormer-B2, 4-channel input (RGB + normalized DSM), 9 classes
(background, RCC_roof, tile_roof, tin_roof, thatched_roof, road_pucca, road_kaccha,
water_body, vegetation). Framework: MMSegmentation or HuggingFace Transformers.
Geospatial stack: rasterio, GDAL, geopandas, shapely. Outputs: COG rasters + GPKG
vectors. Experiment tracking: W&B. Compute: Google Colab A100/T4.
NOTE: No DSM data is currently available. All references to DSM in existing code
should be treated as optional; the model currently runs on RGB only (3 channels).

Please update or extend the existing training and inference scripts to incorporate
the following five enhancements. Treat each as a separate, clearly commented
code section or function so they can be toggled independently via a
FEATURES_ENABLED dict at the top of the inference script.

1. CONFIDENCE MAP OUTPUT
During inference, alongside the argmax class prediction mask, output a second
float32 band representing per-pixel confidence (softmax probability of the
predicted class). Save this as a second band in the output COG, or as a
separate single-band COG named {village_id}_confidence.tif. Also compute
per-tile mean confidence and flag tiles where mean confidence < 0.65 as
"low confidence" in a CSV log: {village_id}_low_confidence_tiles.csv with
columns [tile_id, row, col, mean_confidence, geom_wkt].
Add a GPKG attribute confidence (float, 0.0-1.0) to all output polygons,
computed as the mean confidence of pixels within each polygon.
Also implement optional Monte Carlo Dropout uncertainty: if MC_DROPOUT = True,
run inference N=5 times with dropout active, compute per-pixel entropy across
runs as an additional uncertainty metric, save as {village_id}_uncertainty.tif.

2. TILE CONTEXT INFERENCE (3x3 neighbourhood re-inference)
After the initial inference pass, for all tiles flagged as low confidence
(mean confidence < 0.65), construct a 3x3 superpatch by stitching the tile
with its 8 spatial neighbours (handle edge tiles by reflection padding).
Run inference on the full 1536x1536 superpatch, then crop back to the centre
512x512 region and replace the original low-confidence prediction with this
context-aware prediction. Update the confidence map accordingly.
Toggle: FEATURES_ENABLED['context_inference'] = True/False.
Log how many tiles were re-processed per village.

3. EDGE-ADJACENT TILE CLASS TRACKING (boundary conditioning)
After the initial inference pass (or after context inference if enabled),
apply a boundary conditioning post-processing step:
- For each tile, extract the dominant predicted class along each of its
  4 edges (top, bottom, left, right), using a 16-pixel strip.
- For any edge pixel in that tile where confidence < 0.70 AND the adjacent
  tile's corresponding edge strip has a different high-confidence class
  (confidence > 0.80), apply a soft bias toward the adjacent class by
  blending the logits: blended = 0.6 * original + 0.4 * adjacent_class_prior.
- Re-compute the argmax on blended logits for those edge pixels only.
- This encourages spatial consistency across tile boundaries without
  retraining the model.
Toggle: FEATURES_ENABLED['edge_conditioning'] = True/False.

4. ROAD CONNECTOR POST-PROCESSING
After polygonizing and converting road predictions (road_pucca and road_kaccha
```

```
classes) to LineString geometries in the GPKG, apply a gap-closing step:
- Find road segment endpoints within 15 metres of another segment endpoint
- Check that the gap region does not contain high-confidence building or
  water predictions (confidence > 0.75 in confidence mask)
- If clear, insert a connecting LineString segment to close the gap
- Add attribute road_connector: True to distinguish inserted segments
  from model-predicted ones
Use shapely and geopandas. Operate on the roads layer of the GPKG in-place.
Toggle: FEATURES_ENABLED['road_connector'] = True/False.

5. REGION-AWARE PARAMETER CONFIG
Create a config file region_params.yaml that defines per-region overrides for:
class loss weights, confidence thresholds per class, minimum polygon area
for cleanup (m2), and road gap-closing distance (m).
Define these regions: semi_arid_north, humid_east, peninsular_south, coastal.
Load this config at the start of both training and inference, selecting the
active region via REGION = "semi_arid_north" at the top of the script.
Document each parameter with inline comments explaining the rationale
(e.g. kaccha roads in semi_arid_north have pale sandy spectral signature
similar to background soil, increase road_kaccha loss weight to 4.0).

Additionally: add a post-processing rule for spectrally ambiguous water bodies
(moss/algae covered, no DSM available). After the main prediction pass, flag
any polygon classified as vegetation that meets ALL of:
  (a) area > 500 m2
  (b) shape compactness (4*pi*area / perimeter^2) > 0.45 (smooth, regular)
  (c) more than 30% of its boundary pixels are adjacent to water_body class
Reassign class to water_body and add attribute surface_condition:
"partially_obscured" in the GPKG buildings layer is NOT affected —
apply only to the vegetation and water_body layers.

Keep all existing functionality intact. Add FEATURES_ENABLED at the top:
FEATURES_ENABLED = {
    'confidence_maps': True,
    'mc_dropout': False,
    'context_inference': True,
    'edge_conditioning': True,
    'road_connector': True,
    'region_params': True,
    'water_body_recovery': True
}
Log which features are active at the start of each run.
```

Section 3 — Literature Review

This section provides academic grounding for four of the five strategies, prioritised by the depth of existing literature. Each subsection covers the key findings, representative papers, and direct applicability to this project. Where relevant, limitations or caveats are noted.

3.1 Uncertainty Quantification & Confidence Maps

Uncertainty quantification in deep learning segmentation is a well-developed field, with particularly strong representation in remote sensing and Earth observation contexts. The central problem — that standard deep neural networks are overconfident and provide no signal about when their predictions should not be trusted — is directly addressed by Bayesian deep learning methods.

Monte Carlo Dropout (MCD)

Gal & Ghahramani (2016) ("Dropout as a Bayesian Approximation", ICML 2016) established the theoretical foundation: keeping dropout active at inference time is mathematically equivalent to approximate variational Bayesian inference in a Deep Gaussian Process. This means N forward passes with dropout produce a predictive distribution over classes rather than a single point estimate. The variance of this distribution is the *epistemic uncertainty* — what the model doesn't know.

Dechesne, Lassalle & Lefèvre (2021) ("Bayesian U-Net: Estimating Uncertainty in Semantic Segmentation of Earth Observation Images", Remote Sensing 13(19)) directly applied MCD to aerial image segmentation. Key findings:

- Achieved F1-score 90.84% and overall accuracy 93.22% on the ISPRS Potsdam benchmark — competitive with deterministic baselines
- Uncertainty maps showed strong correlation with prediction errors: high-uncertainty pixels were disproportionately the incorrectly labelled ones
- Demonstrated that removing the top 20% most uncertain pixels from the output increased the precision of remaining predictions substantially
- Showed that **MCD networks learn more accurately from noisy labels** — directly relevant to the annotation quality challenges in this project
- Presented a practical database correction application: flagging uncertain regions for human review and correction

Relevance to this project: this paper is almost a direct analogue of the proposed confidence map and surveyor tool strategy. The ISPRS Potsdam dataset (urban aerial imagery, 5cm/pixel, multiple land cover classes) is structurally similar to SVAMITVA orthophotos. The "database correction" use case described in the paper is exactly the proposed surveyor feedback loop.

Alternative uncertainty methods

While MC Dropout is the most tractable approach for this project, two alternatives are documented for completeness:

- **Deep Ensembles**: train N independent models on the same data with different random seeds. Ensemble disagreement is the uncertainty estimate. More expensive but produces better-calibrated uncertainties. Not practical for the hackathon timeline but worth noting for production deployment.
- **Test-Time Augmentation (TTA)**: run inference on multiple augmented versions of the same tile (rotations, flips) and measure prediction variance. Already planned as a TTA step for accuracy improvement — trivially extended to produce uncertainty estimates at no additional cost.

Key literature table — uncertainty quantification

Reference	Key contribution	Relevance to project
Gal & Ghahramani 2016 (ICML)	Theoretical basis for MC Dropout as Bayesian inference	*Justifies MCD as principled uncertainty method*

Reference	Key contribution	Relevance to project

Hüllermeier & Waegeman 2021 (AI Review)	Survey of epistemic vs aleatoric uncertainty in deep NNs	*Conceptual framework for interpreting confidence outputs*

3.2 Tile Context Inference & Tiling Artefacts

Tile-based inference of large images is a widely studied problem in both remote sensing and biomedical imaging. The consensus finding is that **larger spatial context at inference time produces more consistent and accurate predictions**, particularly near tile boundaries and for under-represented classes.

Foundational problem characterisation

Baumgartner et al. (2020) ("Systematic Evaluation of Image Tiling Adverse Effects", Frontiers in Neuroscience) provided a rigorous evaluation of tiling artefacts in fully convolutional networks. Key findings directly applicable to this project:

- Tile size, offset, and overlap can cause large variations in predictions, particularly at tile borders
- Larger tile sizes (more context) **consistently yield more consistent results** — the improvement is gradual as context increases
- Standard 50% overlap with logit averaging (not hard argmax per tile) substantially reduces boundary artefacts
- The 3D U-Net experiments showed that including more spatial context along additional dimensions always improved performance — this is the direct theoretical basis for the 3×3 superpatch approach

Kowal et al. (2024) ("Exact Tile-Based Segmentation Inference", NIST JRES 126) formalised the halo/context zone approach:

- For any pixel to receive its full context, the input tile must extend beyond it by at least half the network's receptive field
- Proposed the Zone of Responsibility (ZoR) concept: infer on a larger tile (ZoR + halo), use only the central ZoR crop for stitching
- This is the formal equivalent of the 3×3 superpatch strategy: the **central 512×512 tile is the ZoR**, the surrounding 8 tiles provide the halo context

Earth observation specific findings

Dalsasso et al. (2024) ("A Concise Tiling Strategy for Preserving Spatial Context", ICLR ML4RS) proposed Flip-n-Slide specifically for satellite imagery:

- Multiple overlapping views at different positions, each with a distinct rotation/reflection permutation
- Particularly effective for **under-represented classes** — improved precision by up to 15.8% for rare classes (polar moss/lichen)
- Directly validates the idea that spatial context is especially important for class disambiguation in geospatial segmentation

Weber et al. (2023) ("Geo-Tiles for Semantic Segmentation", arXiv:2306.00823) introduced the concept of *reliable pixel regions* within tiles:

- Pixels near the centre of a tile receive more context than edge pixels and have statistically better predictions
- Proposed a tile substitution approach: replace edge-pixel predictions with the equivalent centre-pixel predictions from adjacent tiles
- This is the **theoretical basis for the edge-adjacent tile tracking strategy**: edges are inherently less reliable and should be informed by their neighbours

Key literature table — tile context inference

Reference	Key contribution	Relevance to project
Baumgartner et al. 2020 (Front. Neuroscience)	Systematic evaluation of tiling artefacts; larger context always improves consistency	*Direct justification for 3×3 superpatch re-inference*
Kowal et al. 2024 (NIST JRES)	ZoR + halo approach for error-free tile inference; half-receptive-field halo required	*Formalises the superpatch context requirement*

Aichert et al. 2024 (arXiv)	Tiling artefacts and normalisation; tile mismatch as measurable metric	*Motivates logit averaging over hard argmax in overlap zones*

3.3 Edge-Adjacent Tile Class Tracking & Spatial Boundary Conditioning

The proposed strategy — conditioning edge-pixel predictions on adjacent tile's class distributions — sits at the intersection of two well-studied areas: **Conditional Random Fields (CRF)** for spatial consistency in segmentation, and **boundary-aware segmentation architectures** for aerial imagery.

CRF-based spatial consistency

Chen et al. (2018) (DeepLabV3+) and the broader DeepLab series popularised the combination of CNN segmentation with CRF post-processing. Dense CRFs enforce the principle that *nearby pixels with similar colour should have the same label*. The proposed edge conditioning strategy is a coarser, inter-tile version of this principle: *edge pixels with adjacent-tile neighbours that are consistently labelled should match that label unless strongly contrary evidence exists*.

Mnih (2013) ("Machine Learning for Aerial Image Labeling", PhD thesis) — one of the earliest deep learning road segmentation papers — explicitly predicted a small central patch given a larger local context window, exactly the local-context-for-edge-pixel principle underlying the proposed strategy. Later work by Saito et al. (2016) extended this with model averaging across multiple offset predictions.

Boundary-aware aerial segmentation

Marmanis et al. (2016) ("Classification with an Edge", ISPRS JPRS) showed that making class boundaries explicit in the model — training a boundary detection head alongside the segmentation head — was **the single most important performance improvement** in their final model on ISPRS Vaihingen and Potsdam. This supports the general principle that explicit boundary treatment improves aerial segmentation quality.

Mao et al. (2020) ("Aerial Image Semantic Segmentation using DCNN Predicted Distance Maps", ISPRS JPRS) proposed predicting signed distance maps — where each pixel's value is its distance to the nearest class boundary. Positive values are inside the correct class, negative are outside. Since neighbouring pixels in distance maps have similar values, the segmentation results are smoother and boundary-consistent — a direct parallel to what the edge conditioning strategy achieves via a different mechanism.

Class relationship modelling

He et al. (2004) / Yang & Förstner (2011) established multi-granular CRF models that encode spatial relationships between classes at multiple scales — fine-grained pairwise consistency and coarse-grained class co-occurrence patterns. The proposed edge conditioning is a practical approximation of the coarse-grained co-occurrence constraint: if 'water body' is consistently predicted on one side of a tile edge, 'vegetation' on the immediate other side is more likely to be aquatic vegetation or mud flat than terrestrial vegetation.

Key literature table — edge conditioning & spatial consistency

Reference	Key contribution	Relevance to project
Chen et al. 2018 (DeepLabV3+)	CRF post-processing for spatial consistency; colour similarity drives label smoothing	*Theoretical basis for cross-tile consistency conditioning*
Weber et al. 2023 (Geo-Tiles)	Reliable pixel regions; edge pixels need adjacent context for accurate prediction	*Direct support for edge conditioning priority at tile boundaries*
Marmanis et al. 2016 (ISPRS JPRS)	Boundary-aware segmentation as multitask learning; boundary detection was single biggest improvement	*Validates importance of explicit boundary treatment in aerial segmentation*
Mao et al. 2020 (ISPRS JPRS)	Distance maps encode spatial context; smoothness constraints via predicted distances	*Alternative spatial consistency mechanism; validates inter-pixel spatial constraints*
He et al. 2004 / Yang & Förstner 2011 (CVPR/ICCV)	Multi-granular CRF with class co-occurrence patterns across scales	*Conceptual basis for class-relationship priors in edge conditioning*

3.4 Domain Adaptation & Region-Wise Parameter Adjustment

The geographic diversity of India — spanning semi-arid, humid tropical, coastal, and highland agro-climatic zones — represents a severe **domain shift** problem for a single trained model. This is one of the most actively researched problems in remote sensing deep learning, typically studied as *Unsupervised Domain Adaptation (UDA)* or *Domain Generalisation*.

The domain shift problem in remote sensing

Wurm et al. (2021) and others have documented that models trained on **one geographic region frequently fail catastrophically on another** — even within the same country — due to differences in building morphology, road surface materials, vegetation types, and soil colour. For SVAMITVA specifically, the challenge is that training data from 10 villages will inevitably represent a narrow slice of India's geographic diversity.

Benjdira et al. (2019) / Zeng et al. (2024) ("Weakly-supervised domain adaptation for built-up region segmentation") proposed adapting both latent space and output space with only image-level weak labels from the target domain. The mean-teacher framework with prototype classifiers (MTA) addresses class distribution inconsistencies between source and target domains — the exact problem of training on Bihar villages and inferring on Kerala villages.

Practical parameter adjustment approaches

Full UDA (retraining with adversarial objectives) is out of scope for the hackathon. However, parameter-level adaptation is feasible and documented:

- **Instance Batch Normalisation (IBN)** (Wang et al. 2022, DeepLabV3+ variant) — applying style-normalisation in the backbone to reduce spectral domain sensitivity. This is a training-time choice but requires only a change to the backbone configuration, not retraining from scratch

- **Confidence threshold adaptation** — the minimum confidence for accepting a road prediction should be higher in regions where road and background soil are spectrally similar. This is a test-time parameter requiring no retraining
- **Class weight adaptation** — regional prevalence of minority classes (thatched roofs in humid east, kaccha roads in semi-arid zones) should inform loss function class weights during fine-tuning on regional data

LoveDA dataset relevance

Wang et al. (2021) ("LoveDA: A Remote Sensing Land-Cover Dataset for Domain Adaptive Semantic Segmentation", NeurIPS 2021 Datasets track) is the most directly relevant benchmark dataset — it was specifically designed to study urban-to-rural domain adaptation in aerial imagery. Key findings:

- Performance drops of 10–20 mIoU points are typical when transferring a model trained on one geographic region to another
- Class-level performance degradation is highly uneven — common classes (background, road) are relatively stable; rare and morphologically variable classes (buildings in different construction styles) drop sharply
- The **domain gap between rural sites within the same country** can be as large as the gap between different countries

Proposed regional config as a lightweight solution

Rather than full UDA (which requires target domain data), the *region_params.yaml* approach implements a knowledge-based approximation: domain experts and field contacts (such as the EMPRI contact and Gram Chetna's experience in Bihar villages) inform the parameter choices for each region. This is **domain knowledge injection at inference time** — a pragmatic solution that scales without additional annotated data and demonstrates regional awareness that judges will recognise as thoughtful engineering.

Key literature table — domain adaptation

Reference	Key contribution	Relevance to project
Wang et al. 2021 (NeurIPS — LoveDA)	Land cover dataset explicitly for rural-urban domain adaptation; 10-20 mIoU drop typical across regions	*Quantifies the cross-region degradation problem this strategy addresses*
Benjdira et al. 2019 / Zeng et al. 2024 (ISPRS JPRS)	Weakly-supervised and prototype-based UDA for built-up segmentation; both latent and output space adaptation	*Full UDA reference if dataset expands; validates domain shift severity*
Wang et al. 2022 (Deep Learning RS review)	IBN modules in DeepLabV3+ for style-domain normalisation in RS imagery	*Training-time backbone modification for regional generalisation*

3.5 Synthesis: How the Strategies Fit Together

The five strategies form a **coherent layered system** rather than independent additions. Understanding how they interact is important for both implementation ordering and for articulating the innovation in the submission document.

Strategy	When it operates	Feeds into
Region config	At startup — sets all thresholds	Confidence thresholds, loss weights, cleanup params
Confidence maps	During initial inference pass — all tiles	Context inference (flags tiles), edge conditioning (gates edge pixels), surveyor tool
Context inference (3×3)	Second pass — low-confidence tiles only	Updated predictions fed to edge conditioning and polygonization
Edge conditioning	Post context inference — edge pixels only	Smoother tile-boundary predictions going into polygonization
Road connector	Post-polygonization — vector layer	Final GPKG output — roads layer
